

Alternative splicing leaves most IDR exons intact; among those remodeled, removal exceeds addition — equally in TFs and non-TFs

Every IDR exon ($\text{idr_frac} \geq 0.5$) in a canonical↔alternative comparison is conserved (present in both), removed (canonical only), or added (alternative only) — a clean partition per comparison. Counts are per comparison ($n = 4,204$ genes, 10,151 canonical↔alternative comparisons); removed/added reproduce the Step-10 splice events. b, TF vs non-TF fate distribution tested by χ^2 on a 2×3 (TF/non-TF $\times$ conserved/removed/added): $P = 0.75$ (n.s.), Cramér's $V = 0.004$ (negligible effect).
