

Older TFs conserve their IDR exons and stop gaining new ones; non-TFs stay flat

conserved (in both) removed (canonical only) added (alternative only)

Every IDR exon ($\text{idr_frac} \geq 0.5$) in a canonical↔alternative comparison is conserved (in both isoforms), removed (canonical only), or added (alternative only). Bars are the fate composition within each gene-age bin. In TFs the fate distribution shifts with age ($\chi^2 P = 5 \times 10^{-12}$, Cramér's $V = 0.078$); in non-TFs the shift is negligible ($V = 0.022$). The $\approx 4:1$ removal-over-addition bias holds at every age.
