

Alternative exons have higher IDR fraction than constitutive — in both TFs and non-TFs

Continuous per-exon idr_frac (fraction of residues predicted disordered), not thresholded; one row per UNIQUE exon (deduplicated across isoforms by gene+exon). a, mean $\pm$ 95% CI; stars = alternative vs constitutive within cohort (Mann-Whitney, one-sided): non-TF $P < 10^{-300}$, TF $P = 1.9 \times 10^{-24}$. b, split violins (KDE); solid line = median, dashed lines = quartiles (Q1, Q3), each spanning the violin's width at that value. Distribution is bimodal (exons are mostly fully ordered or fully disordered), so medians sit at 0 or ~1 while the means in panel a fall between.
